CS88 Final Study Guide - Page 1

```
Numeric types in Python:
                                              List comprehensions:
                                                [<map exp> for <name> in <iter exp> if <filter exp>]
 >>> type(2)
                     Represents
 <class 'int'>
                      integers
                                                                                                                   List & dictionary mutation:
                                                 Short version: [<map exp> for <name> in <iter exp>]
                       exactly
                                                                                                                 >>> a = [10]
                                                                                                                                      >>> a = [10]
 >>> type(1.5)
                                              A combined expression that evaluates to a list using this
                                                                                                                 >>> b = a
                                                                                                                                      >>> b = [10]
 <class 'float'><
                                              evaluation procedure:
                   Represents real
                                                                                                                 >>> a == b
                                                                                                                                      >>> a == b
                                              1. Add a new frame with the current frame as its parent
                       numbers
                                                                                                                 True
                                                                                                                                      True
 >>> type(1+1j)
                                              2. Create an empty result list that is the value of the
                    approximately
                                                                                                                                      >>> b.append(20)
                                                                                                                 >>> a append(20)
 <class 'complex'>
                                                expression
                                                                                                                 >>> a == b
                                                                                                                                      >>> a
                                              3. For each element in the iterable value of <iter exp>:
                                                                                                                                       [10]
                                                                                                                 True
                                                A. Bind <name> to that element in the new frame from step 1
Rational implementation using functions:
                                                                                                                                      >>> b
                                                                                                                 >>> a
                                                B. If <filter exp> evaluates to a true value, then add
                                                                                                                  [10, 20]
                                                                                                                                      [10, 20]
def rational(n, d):
                                                   the value of <map exp> to the result list
                                                                                                                 >>> b
                                                                                                                                      >>> a == b

```
Python object system:
Idea: All bank accounts have a balance and an account holder;
the Account class should add those attributes to each of its instances
                        >>>> a = Account('Jim')
   A new instance is
                         >>> a.holder
 created by calling a
                         'Jim'
         class
                         >>> a balance
                                                 An account instance
When a class is called:
                                            balance: 0
                                                          holder: 'Jim'
1.A new instance of that class is created:
2. The __init__ method of the class is called with the new object as its first
  argument (named self), along with any additional arguments provided in the
  call expression.
                     class Account:
                        >def ___init__(self, account_holder):
   _init__ is called a
                             self.balance = 0
      constructor
                             self.holder = account holder
                         def deposit(self, amount):
                             .self.balance = self.balance + amount
                             return self.balance
  self should always be
                         def withdraw(self, amount):
 bound to an instance of
                             if amount > self.balance:
 the Account class or a
                                 return 'Insufficient funds'
   subclass of Account
                             self.balance = self.balance - amount
                             return self.balance
                      >>> type(Account deposit)
                      <class 'function'>
 Function call: all
                      >>> type(a.deposit)
  arguments within
                      <class 'method'>
     parentheses
                      >>> Account deposit(a, 5)
  Method invokation:
  One object before
                      >>> a deposit(2)
  the dot and other
                                                  Call expression
   arguments within
     parentheses
                            Dot expression
                           <expression> . <name>
 The <expression> can be any valid Python expression.
 The <name> must be a simple name.
 Evaluates to the value of the attribute looked up by <name> in the object
that is the value of the <expression>.
 To evaluate a dot expression:
     Evaluate the <expression> to the left of the dot, which yields
     the object of the dot expression
 2. <name> is matched against the instance attributes of that object;
     if an attribute with that name exists, its value is returned
 3. If not, <name> is looked up in the class, which yields a class
     attribute value
4. That value is returned unless it is a function, in which case a
     bound method is returned instead
  Assignment statements with a dot expression on their left—hand side affect
  attributes for the object of that dot expression

    If the object is an instance, then assignment sets an instance attribute

  • If the object is a class, then assignment sets a class attribute
          Account class
